A thirty-three-year-old male presented to an outside emergency department with scrotal swelling and pain after intercourse. A scrotal ultrasound revealed hematoma, with no other abnormalities and the patient was discharged. He then presented to our institution where examination showed diffuse ecchymosis through the shaft of the penis, suprapubic region, and scrotum without a palpable cavernosal defect.

Magnetic resonance imaging (MRI) without contrast was obtained after the injection of 10 micrograms of intracavernosal alprostadil. The low signal tunica albuginea is easily demarcated compared to the high T2 and intermediate T1 signal of the corpora cavernosum (Figures 1-3) (1,2). Hematoma shows heterogeneous intermediate T1 and T2 signal (Figures 2 and 3) (1).

Penile fracture is rupture of the corpus cavernosum from blunt trauma to the erect penis (3,4). Typical presentation is a pop during intercourse, immediate detumescence with edema, hematoma and penile deformity (3,4). In atypical presentations, radiological studies may be useful to determine the diagnosis. MRI provides the ability to identify disruption of the corpus cavernosum due to excellent tissue contrast and

Figure 1 - Coronal T1 image shows disruption of the low intensity inferior left tunica albuginea and associated low signal corpus cavernosal hematoma at the base of the penis.

Figure 2 - The heterogeneous left scrotal hematoma and low signal left corpus cavernosum hematoma are more conspicuous on this T2 coronal image.
visualization of soft tissue pathological processes (5). MRI is an adjunctive tool in the evaluation of atypical presentations of suspected penile fracture (3).
