ABSTRACT

Objective: The aim of active surveillance of early prostate cancer is to individualize therapy by selecting for curative treatment only patients with significant cancer. Epstein’s criteria for prediction of clinically insignificant cancer in surgical specimens are widely used. Epstein’s criterion “no single core with >50% cancer” has no correspondence in linear extent. The aim of this study is to find a possible correspondence.

Materials and Methods: From a total of 401 consecutive patients submitted to radical prostatectomy, 17 (4.2%) met criteria for insignificant cancer in the surgical specimen. The clinicopathologic findings in the correspondent biopsies were compared with Epstein’s criteria for insignificant cancer. Cancer in a single core was evaluated in percentage as well as linear extent in mm.

Results: Comparing the clinicopathologic findings with Epstein’s criteria predictive of insignificant cancer, there was 100% concordance for clinical stage T1c, no Gleason pattern 4 or 5, ≤2 cores with cancer, and no single core with >50% cancer. However, only 25% had density ≤0.15. The mean, median and range of the maximum length of cancer in a single core in mm were 1.19, 1, and 0.5-2.5, respectively. Additionally, the mean, median, and range of length of cancer in all cores in mm were 1.47, 1.5, and 0.5-3, respectively.

Conclusion: To pathologists that use Epstein’s criteria predictive of insignificant cancer and measure linear extent in mm, our study favors that “no single core with >50% cancer” may correspond to >2.5 mm in linear extent.

INTRODUCTION

Due to widespread of PSA screening, an increasing number of T1c prostate carcinomas are diagnosed as well as the so-called clinically insignificant tumors. Many of these malignancies would most probably not have caused any symptoms during a man’s lifetime if they had remained undiagnosed. This so-called overdiagnosis due to screening often results in overtreatment, subjecting men to unnecessary costly and invasive treatment with risk of important side effects (1). The aim of active surveillance of early prostate cancer is to individualize therapy by selecting for curative therapy only patients with significant cancer (2). The best possible selection of patients with prostate cancer with low risk progression is the main factor for a successful active surveillance.
Epstein’s criteria on biopsies for prediction of clinically insignificant cancer in the radical prostatectomy specimens are widely used (3, 4). The criteria include: clinical stage T1c, PSA density ≤0.15, no Gleason score 4 or 5, ≤2 biopsy cores with cancer, and ≤50% cancer per core. An alternative measure to the latter criterion is to evaluate the maximum length in mm of cancer per core. A survey among pathologists showed that an estimate of the linear extent of cancer in a core was made by 81% (5). This assessment was most often given in millimeters for each core by 53% followed by estimation of percentage of cancer in each core by 39%.

Considering that a high number of pathologists evaluate tumor extent on biopsies in millimeters, which length in mm corresponds to ≤50% cancer per core when using Epstein’s criteria? The aim of this study is to find this possible correspondence.

**MATERIALS AND METHODS**

This retrospective study was based on prostate specimens from 401 patients submitted to radical retropubic prostatectomy by one surgeon (UF). All biopsies and surgical specimens were reviewed by a senior uropathologist (AB). The tumors were graded according to the 2005 International Society of Urological Pathology (ISUP) modified Gleason score values (6). After radical prostatectomy, serum PSA was drawn every 3 months during the first year, every 6 months during the second year, and annually thereafter. No patient of this series had radiotherapy or androgen manipulation before or after surgery. Total serum PSA was measured utilizing previous validated Immulite® PSA kit. Biochemical recurrence following surgery was considered as PSA ≥0.2 ng/mL with a second confirmatory level of PSA >0.2 ng/mL according to recommendation of the American Urological Association (7). Patients without evidence of biochemical recurrence were censored at last follow-up. The present study was approved by the Institutional Committee of Ethics of our Institution.

The surgical specimens were step-sectioned at 3 to 5 mm intervals and totally embedded in paraffin. A mean of 32 paraffin blocks were processed and 6 µm sections from each block were stained with hematoxylin and eosin. Each transverse section of the prostate was subdivided into 2 anterolateral and 2 posterolateral quadrants. Using the cone method, 8 sections from the bladder neck and 8 sections from the apex were obtained.

Positive surgical margin was defined as cancer cells in contact with the inked specimen surface. Extraprostatic extension was diagnosed whenever cancer was seen in adipose tissue and, in case of desmoplastic response, whenever a protrusion corresponding to extension of tumor into periprostatic tissue was seen. Seminal vesicle invasion occurred whenever there was involvement of the muscular coat. Tumor extent at radical prostatectomy was evaluated by a semiquantitative point-count method previously described (8). Briefly, drawn on a sheet of paper, each quadrant of the transverse sections contained 8 equidistant points. During the microscopic examination of the slides, the tumor area was drawn on the corresponding quadrant seen on the paper. At the end of the examination the amount of positive points represented an estimate of the tumor extent. A total of ≤10 positive points (minimal tumor extent) correspond to ≤0.5 cm² tumor.

We defined insignificant cancer in radical prostatectomy, patients with organ-confined tumor (p T2), ≤0.5 cm³ tumor (minimal tumor extent), negative surgical margins, and Gleason score ≤6. Several clinicopathologic findings of the patients were studied: age, race, clinical stage, preoperative serum PSA, weight of the prostate in surgical specimen; pathologic PSA density (serum PSA/weight of the prostate in surgical specimen); and, on the correspondent needle biopsies number of cores with cancer, maximum percentage of cancer in a single core, maximum length of cancer in a single core in mm, length of cancer in all cores in mm, and number of cores. Linear extent of carcinoma in mm was measured using a single Olympus (Olympus Optica Co., Ltd., Tokyo, Japan) micrometer eyepiece with a linear array. In cases of discontinuous foci 1 mm apart, the tumor was considered as continuous and the measure included 1 mm. In discontinuous foci more than 1 mm apart, the final extent was the sum of the measures.
RESULTS

From 401 consecutive patients submitted to radical prostatectomy over a period of 13.8 years, 17 (4.2%) patients met criteria for insignificant cancer in the surgical specimens. The mean follow-up after surgery of these 17 patients was 81 months (median 79, range 32-148). All patients were clinical stage T1c and no patient during this period had biochemical recurrence. The mean and median age (range) was 61 and 64 (46-70) years. From the total of 17 patients, 12 (70.6%) were Whites and 5 (29.4%) were African-Brazilians. From the total of 17 needle biopsies, 12 were extended. The mean and median number of cores was 10 and 9, respectively.

The clinicopathologic findings in these 17 patients are shown in Table-1. The mean, median and range of the maximum length of cancer in a single core in mm were 1.19, 1, and 0.5-2.5, respectively. No core showed length of cancer >2.5 mm.

Additionally, the mean, median, and range of length of cancer in all cores in mm was 1.47, 1.5, and 0.5-3, respectively. In no biopsy the length of cancer in all cores was >3 mm. Figure-1 illustrates a focus of adenocarcinoma in a biopsy core; it measures 0.5 mm corresponding to 4.5% of the total linear extent of the fragment which measured 11 mm.

In Table-2 we compare the clinicopathologic findings with Epstein’s criteria on needle biopsy predictive of insignificant cancer in surgical specimens. The findings were concordant in 100%, 100%, 100%, 100%, and 24% patients for stage T1c, no Gleason pattern 4 or 5, ≤2 cores with cancer, no core with >50% cancer, and PSA density ≤0.15, respectively.

DISCUSSION

In this novel approach we found that comparing the findings of 17 prostatectomy specimens with insignificant cancer, there was 100% concordance with Epstein’s predictive criteria on biopsies for clinical stage T1c, no Gleason pattern 4 or 5, ≤2 cores with cancer, and no core with >50% cancer per core. The mean and median (range) maximum length in a single core in mm was 1.2 and 1 (0.5-2.5). No single core in the biopsy showed cancer length >2.5 mm. An additional finding was a maximum length not more than 3 mm considering the 2 cores.

A review article has stated that no optimal method is available but advises measurements of tumor burden being in millimeters as well as percentage terms (9). We consider that the correspon-
The frequency of insignificant cancer in radical prostatectomy surgical specimens in our study was 4.2%. Sengupta S et al. found a frequency of...
5.5% (14), Augustin H et al. 5.8% (15), and Loeb S et al. 2.6% (16). No patient had biochemical recurrence in a mean follow-up period after surgery of 81 months (median 79, range 32-148). The clinicopathologic findings of these patients favor a very low risk cancer and could have been candidates for active surveillance.

The only discrepancy with Epstein’s criteria in our findings was related to PSA density. The mean and median (range) was 0.19, 0.17 (0.11-0.27). According to our result, a cutoff for PSA density ≤0.15 seems to be very restrictive. Most entry criteria for active surveillance consider PSA density <15 ng/mL but others, however, consider higher cutoffs (1, 15-22). The entry criteria for active surveillance in the PRIAS study include: clinical stage T1c-T2b, no Gleason pattern 4 or 5, fewer than 3 positive cores, serum PSA <10 ng/mL, and PSA density <0.20 ng/mL/cm³ (1). We must consider, however, that in our study PSA density was calculated by dividing preoperative PSA level by prostate weight in surgical specimen and in most studies the weight (volume) of the prostate is calculated by ultrasound. In spite of studies showing that the correlation between pathologic PSA density and actual PSA density using transrectal ultrasound is almost perfect (3, 23), these different measures may influence the results.

The serum PSA level is also variably considered in entry criteria for active surveillance. It may be considered <10 ng/mL, <15 ng/mL, and even not considered as an entry criterion (1, 3, 17, 18, 20, 21). In our study the mean, and median (range) preoperative serum PSA value was 7.8, and 7.3 (4.5-12.30) ng/mL.

Some study limitations warrant discussion. The follow-up could be longer, however considering the favorable clinicopathologic findings (clinical stage T1c, organ-confined tumor, no Gleason 4 or 5, no positive surgical margins, and the minimal tumor extent, the probability of biochemical recurrence can be considered highly improbable.

These patients belong to the very low risk group for biochemical recurrence and could have been candidates for active surveillance. The study was based on a small number of patients. The low frequency of 4.2% for this group of patients submitted to radical prostatectomy was between 2.6% and 5.8% of other studies (14-16) and in our study reflects the involvement of our Institution in proposing to patients with criteria for insignificant cancer, active surveillance instead of definitive treatment. Not all needle biopsies were extended 12-core. From the total of 17 needle biopsies, 12 were extended; the mean and median number of cores was 10 and 9. In case all needle biopsies were extended, results could have been different. Therefore, other studies with only extended biopsies and higher number of patients are needed to support our study. We must consider, however, that in Epstein’s original 1994 study the median number of cores sampled was 5 and the results were valid in the contemporary analysis of 2011 with extended biopsies (3, 4).

CONCLUSIONS

From a total of 401 patients submitted to radical prostatectomy, 17 harbored insignificant cancer in the surgical specimen. Comparing the clinicopathologic findings with Epstein’s criteria on needle biopsies predictive of insignificant cancer, there was 100% concordance for clinical stage T1c, no Gleason pattern 4 or 5, ≤2 cores with cancer, and no single core with >50% cancer. However, only 24% had density ≤0.15.

We found that Epstein’s criterion of “no single core with >50% cancer” corresponded to >2.5 mm in linear extent. An additional finding was a maximum length not more than 3 mm considering all cores. This correspondence is important because many pathologists estimate linear extent in mm of cancer instead of percentage. To pathologists that use Epstein’s criteria predictive of insignificant cancer and measure linear extent in mm, our study favors that “no single core with >50% cancer” may correspond to >2.5 mm in linear extent.
