ABSTRACT

AIMS: To determine the growth rate of renal masses (RMs) under active surveillance (AS), and to describe the clinical outcome of AS patients.

Materials and Methods: We conducted a retrospective review of an AS database to obtain demographics, radiological and pathologic characteristics and RM size of patients. RMs were followed at 6–12 month intervals for ≥1 year with computed tomography (CT), magnetic resonance imaging (MRI), or renal ultrasound. Kaplan-Meier analysis determined the annual likelihood of intervention. RMs were divided into 3 radiographic subcategories (solid, cystic, and angiomyolipoma). A linear regression model determined RM growth rates.

Results: 131 RMs in 114 patients were included. Median age, Charlson Comorbidity Index score and mean follow-up were 69.1 years, 4.0 and 4.2±2.6 years, respectively. Maximal tumor diameter (MTD) at diagnosis was 2.1±1.3 cm. 49 RMs exhibited negative or zero net growth. Mean MTD growth rate for all RMs was 0.72±3.2 (95% CI: 0.16–1.28) mm/year. When stratified by MTD at diagnosis, mean RM growth rates were 0.84, 0.84, 0.44, 0.74 and 0.71 mm/year for RMs <1 cm, 1–<2cm, 2–<3cm, 3–<4cm and ≥4cm, respectively (p<0.01). The 5 and 10-year freedom from intervention rates were 93.1% and 88.5%, respectively. There was a single case of suspected metastases, but no deaths related to kidney cancer.

Conclusions: RMs under AS grew slowly, and had a low incidence of requiring surgical intervention and progression. Solid enhancing masses grew slowly, and were more likely to trigger intervention. AS should be considered for selected patients with small RMs.

INTRODUCTION

The use of high resolution cross-sectional imaging has resulted in the detection of an increasing number of small, incidental renal masses (RMs), a significant proportion of which are subsequently found to be benign on pathologic examination (1).

Recent studies have highlighted the benefit of renal preservation in patients undergoing treatment for renal cell carcinoma (RCC) and have demonstrated that RMs typically exhibit slow growth rates and a low incidence of metastatic spread (2,3). These findings suggest that active surveillance (AS) of RM patients may be a viable management strategy, particularly for those patients at greater risk for perioperative complications or chronic kidney disease (4).

Although AS is gaining acceptance as a RM management strategy, standardized protocols...
are lacking, and clinicians may feel compelled towards surgical intervention owing to uncertainty over growth potential and the risk of disease progression. We examined our institutional experience with AS of RMs to characterize their growth and risk of progression, and attempted to risk stratify RMs based on radiologic characteristics at time of diagnosis. It was our objective to utilize these data to optimize active surveillance protocols, with the aim of minimizing the morbidity experienced by patients incidentally diagnosed with RMs.

MATERIALS AND METHODS

The study was approved by the Hartford Hospital Institutional Review Board. Data from 114 patients, with a total of 131 RMs, who underwnt active surveillance (AS) of a RM between January 2002 and June 2011, were retrieved from our IRB-approved renal mass active surveillance database. Patient demographics and clinical, radiologic, and pathologic RM characteristics were tabulated. Patients were diagnosed either incidentally or upon clinical presentation using ultrasonography (US), computerized tomography (CT) or magnetic resonance imaging (MRI). Patient follow-up occurred at 6-12 month intervals using CT, MRI or US. Key factors that influenced undertaking a RM biopsy included (i) growth rate, (ii) the worsening of a suspicious feature on imaging while on AS (i.e., more enhancement or more definitive solid component), (iii) patient preference due to emotional distress/concern and (iv) significant patient comorbidities which would favor AS of RMs based on radiologic characteristics at time of diagnosis. In our institution, RMs are selected for AS to undergo surgery, and RM size and appearance. All patients are counseled that in the event that their RM showed significant growth on follow-up, surgical intervention might be considered. Only patients who were followed for >12 months and had ≥2 imaging procedures on follow-up were included in the analysis.

The maximal tumor diameter (MTD) of RMs imaging was determined, and recorded at time of diagnosis and on each follow-up visit. Specifically, a linear regression model was utilized to construct a “line of best fit” for the growth of each individual mass, and the growth rate was calculated from its slope. The average growth rate of each radiographic RM subgroup was calculated as the mean value of their growth rate slopes. Kaplan-Meier analysis was used to estimate the overall likelihood of requiring intervention. Statistical tests including (i) t-test, (ii) Mann-Whitney U test, (iii) ANOVA, and (iv) Kruskal-Wallis test were used depending on the assumption of homogeneity of the variances. Comparison between the mean RM growth rates of the solid, cystic and AML groups (tests i and ii) and between RMs stratified according to their initial size (tests iii and iv) were performed. The growth rate of RMs with a positive net growth on follow-up, and histopathologically proven to be RCC, was also calculated. All statistical analyses were performed using SPSS version 17.0 (Chicago, IL).

RESULTS

Data from 114 patients under AS (60 female; 52.6 %) for 131 RMs were available and met the study inclusion criteria. In this group, median patient age at diagnosis was 69.1 years (range: 20.7-89.7), median Charlson Comorbidity Index (CCI) score was 4 (range: 0-8), and mean follow-up time was 4.2±2.6 years (range: 0.9-15.3). The mean and median number of follow-up studies was 5.9±3.2 and 6.0, respectively (range 2-17). Patient demographics and RM characteristics are summarized in Table 1. At diagnosis, the mean maximal tumor diameter (MTD) was 2.1±1.3cm (solid: 1.9, 0.7-4; cystic: 2.84±2.1, 0.9-9.2; AML: 1.63±1.16, 0.4-4.6cm). At the most recent patient follow-up visit, the mean MTD was 2.36±1.63cm (solid: 2.18±1.0, 0.3-5.3; cystic 3.13±2.8cm, 0.6-11; AML: 2.04±1.08, 0.4-3.9cm).

Mean MTD growth rate for all RMs was 0.72±3.2 (95% CI: 0.16-1.28) mm/year (solid: 0.94±1.9 (95% CI: 0.5-1.4) mm/year; cystic: 0.1±4.4 (95% CI: -1.63-1.81) mm/year; AML: 0.75±4.4 (95% CI: -1.1-2.6) mm/year; p<0.01 for all pairwise comparisons). The growth curves of RMs under surveillance are plotted in Figure-2. When stratified by MTD at diagnosis, mean RM growth rates were 0.84±1.7 (95% CI: 1.5-3.17), 0.84±1.6 (95% CI: 0.4-4.128), 0.44±2.9 (95% CI: -0.61-1.51), 0.74±1.5 (95% CI: -0.32-1.79) and 0.71±5.7 (95% CI: -2.88-4.3) mm/year for RMs <1cm, 1-<2cm, 2-<3cm, 3-<4cm and ≥ 4 cm at diagnosis, respectively (p<0.01; Figure-3).

Therapeutic intervention was performed on 82 RMs (62.6 %) exhibited positive net growth, while 49 (37.4 %) exhibited negative or zero net growth during AS (solid masses: 25/77, 32.5 %; AMLs: 7/25, 28 % and cystic masses: 17/29, 58.6 %). Therapeutic intervention was performed on 15 RMs initially under AS. Of these, 13 of the masses were solid enhancing masses and two were angiomyolipomas. (Table-2). Interventions performed on these masses included 7 partial nephrectomies, 6 cryoablations, and one selective embolization for AML, at a mean time from diagnosis of 4.77±2.48 years (median: 4.2 years; 1.1-10.48) and at a mean tumor size of 2.83±0.63cm (2-3.8cm) (Table-2). The mean MTD growth rate of RMs eventually undergoing surgical intervention was 2.57±1.2 mm/year. Indications for interventions were mass growth to a MTD >3cm in 5 RMs. The remaining RM underwent cryoablation due to patient anxiety in a mass measuring <2cm with minimal growth. The overall 5 and 10-year freedom from intervention rates were 93.1% and 88.5 %, respectively (Figure-4).
In the present study, we characterized the natural history of RMs under active surveillance and delineated which lesions may be most appropriate to manage under AS. These data may ultimately aid in the refinement of AS inclusion and termination criteria, and help manage risks associated with AS clinical management strategies.

Our data illustrate that RM growth rates under AS were lower than reported in previous studies. There were also clear differences in the MTD growth rate when RMs were stratified based upon their radiologic appearance at diagnosis. While the growth rate of AML lesions was the most rapid, they are clinically benign. AMLs are often managed with AS and subsequent intervention is commonly reserved until tumor size exceeds 4 cm, due to increased risk of bleeding and local symptoms (10). As such, understanding the average growth rate of AMLs is useful for patient counseling. Furthermore, the epithelioid variant of AMLs can behave aggressively, further illustrating the importance of monitoring these lesions (11).

In contrast, complex cystic lesions showed essentially zero growth over the time course of the study period, while solid masses showed an intermediate, yet slow rate of growth. These solid lesions, however, were the most likely to progress to intervention during AS, with the subset of RMs requiring intervention showing a much higher than average MTD growth rate (Figure-1). Pathology from masses undergoing intervention uniformly demonstrated low-grade (1,2) renal cell carcinoma, which carries a low risk of metastasis (12).

Initial RM size at time of diagnosis did not prove to be a useful prognostic indicator of growth rate or metastases, with no cases of metastasis amongst the 12 RMs that were >4cm at diagnosis. This should not be interpreted to mean that T1b masses should be routinely placed under AS, however, since the majority of these were complex cystic RMs. Also, surveillanc-
The slow rate of RM growth in this study may be related to its non-randomized nature, as fast growing RMs may have undergone surgery prior to 1 year under AS and, therefore, did not meet the study inclusion criteria. A separate contributing factor to the slow rates of growth may have been the use of regression analysis rather than simple arithmetic calculation to determine growth rates. Previous studies using regression analysis have reported significantly slower growth rates (approximately 1mm/year) as opposed to approximately 3 mm/year using arithmetic methodology (12). We feel that regression provides a more accurate prediction for renal mass growth over an extended period of time, as it controls for outlier measurements which may skew growth curves constructed from relatively short follow-up intervals.

Importantly, mean growth rate of pathologically proven benign lesions (mostly oncocytomas) and RCC variants did not differ statistically. The strengths of our study include a relatively large single center sample size and follow-up interval, and the inclusion of a number of RMs >4cm in size. In addition, the stratification of RMs based on radiologic appearance enabled us to discern the low progression rate of cystic masses. Limitations of the present study include a lack of randomization and subsequent selection bias of patients on AS. The average patient age and CCI scores were relatively high in our cohort and our findings may not be externally valid to younger and healthier cohorts of RM patients. Our findings may also not be directly applicable to patients with a genetic predisposition to aggressive renal cell carcinoma variants such as hereditary leiomyomatosis and renal cell carcinoma (HLRCC) and succinate dehydrogenase mutation associated kidney cancer (14). An additional potential limitation was our reliance on radiological characteristics to identify potentially malignant lesions, rather than pathology data from RM biopsies. While biopsies were performed on only a small number of patients, improved biopsy yield has led to a recent shift to obtaining biopsies when clinically indicated.

Patient follow-up procedures consisted of a variety of CT, MRI and US imaging. Although we routinely use US when feasible, based upon RM visibility and patient body habitus, and the majority of our patients were imaged at 6 month intervals, we did not prospectively employ a standardized protocol for follow-up imaging. A prospective study utilizing a single cross-sectional imaging modality over a standardized follow-up interval would be ideal, but perhaps not feasible due to costs, variability in renal function and concerns over radiation exposure. Additionally, the favorable clinical outcomes demonstrated in the present study indicate that this may be the preferred imaging modality in terms of cost and safety for AS protocols. Furthermore, RM size using US correlated well with size on CT or MRI in our patients, and in a previous study as well (15). As such, improved AS strategies may ultimately reduce the number of imaging studies required and decrease patient exposure to radiation.

Our retrospective analysis may aid in the refinement of a risk stratification protocol for patients under RM active surveillance, possibly in conjunction with renal mass biopsy and genomic testing to identify higher risk RMs. An improved AS treatment paradigm should promote the goal of nephron sparing by avoiding intervention in masses with a low risk of progression. Patients with low risk RMs may also be followed at longer intervals, resulting in fewer office visits.

CONCLUSIONS

Our data from the active surveillance of RMs over a >3 year median follow-up period demonstrate a low rate of tumor growth, with complex cystic masses exhibiting nearly zero net growth. Solid masses exhibited the highest growth rate, and were also the most likely to trigger surgical intervention. A nephron sparing approach for the management of incidental RMs should routinely include AS as an option in appropriately selected patients. Future studies are needed to delineate which RMs are most suitable for AS, particularly in younger patients.
